Abstract: Daylight performance metrics are moving away from the traditional daylight factor and average illuminance to more climatic-based metrics such as Daylight Autonomy (DA) and Useful Daylight Index (UDI). These metrics offer a better measure of the daylight performance throughout the year and incorporate the varying weather conditions and as such are dubbed climatic-based metrics. However, in hot climates where the ratio of direct to diffuse is highest, achieving these metrics may result in over-heating the spaces. Achieving acceptable climatic-based metrics for the space may result in unacceptable heat gains. The Daylight Autonomy and the Useful Daylight Index do not account for the total amount of lux-hours achieved throughout the year. The solution thus far has been to run coupled-energy and daylight simulations and in order to assess the effect of achieving certain climatic-based metrics on the heat gain and thermal performance of the space. In this paper a new metric is proposed that takes into account the total amount of lux-hours achieved throughout the year and the irradiation for different time step into a single measure. Details about the measure and sample test cases are presented.

Key words: climate-based, simulation, daylight, sustainability

1. Introduction

In order to assess the daylighting performance of a particular design climatic (often called dynamic) daylighting measures are used. These measures relate the degree to which a particular level of required illumination is achieved throughout the year. Since there is a direct relationship between the total amount of lux-hours and thermal heat gains, it may be of importance to develop a metric that rewards achieving the required illuminance levels throughout the year while minimizing the total amount of lux-hours that are achieved in times of the year where cooling may be required for example. This means that the weather conditions at the times in which the designer daylight metrics were computed needs to be taken into consideration. An accurate indication of the weather conditions at different times is cooling and heating degree days. It is therefore desirable to increase the amount of lux-hours when the heating degree days are highest and minimize the lux-hours values during hot times when the cooling degree days are highest, simultaneously while increasing metrics such as the DA and the UDI.

Our aim here is to develop a new measure that takes into account the thermal aspects associated with daylighting. Daylighting and solar thermal gains are often positively correlated. In particular, if a specific design achieves acceptable scores for the climatic-based daylighting measures, then it may be often the case that this can be on the account of exceedingly high thermal gains. A number of previous studies have considered the interrelation between daylight performance and thermal performance such as R. Sullivan et al. (1992) [1] and C. A. Johnson et al. (1999) [2] and more recently Ochoa et al. (2012) [3],

Tsikaloudak et al. (2012) [4], Aldawoud (2013) [5],
Lee and Tavil (2007) [6], Inoue et al. (2008) [7],
Athienitis and Tzempelikos (2002) [8].

Without any particular design treatments, then as
more daylight is achieved the thermal loads would
increase. To examine this, a chart was created to
assume the relation between daylight and thermal load,
as shown in Fig. 1. In Fig. 1, the theoretical values for
the irradiation and the amount of lux-hours achieved
throughout a year for a standard room is plotted. By
increasing the window size the lux-hour increase as
well as the amount of direct and diffuse solar gains of
the space.

The amount of lux-hour increase is one measure of
daylighting performance but as several researchers
have noted before is not a very valid or accurate one.
Hence the need for the climatic-based or dynamic
based measures. It is expected that there is a direct
relationship between the thermal gain and the
daylighting performance for a particular design. The
thermal gains could be measured in many terms, one of
the most direct measures is, for instance, the
cumulative hourly direct irradiation, but on the other
hand we may make use of the several climatic-based
measures.

The relationship may assume a linear or depending
on the actual design parameters, i.e., there may be some
designs that allow for the same daylight performance
but with a varied degree of thermal gains. This happens
in cases where complex fenestrations systems for
example can be used or when specific shading devices
or glazing treatments are utilized. In absence of
complex window designs or treatments it is expected
that this range is minimal. This trend continues until
the maximum value for the daylight measure can be
achieved after which no possible improvements in the
daylight performance can be achieved. The remaining
design cases after this point all increase the amount of
thermal gains with no or even worsening values for the
daylight performance measures.

Some climatic-based or dynamic based measures
may result in worse values after a certain point and
others may reach their maximum value and hold. Those
measures that penalize for over lighting for example
would start to drop while others that do not will hold at
maximum values. This specific trend is explored in this
paper as will be described in the next sections.

The remainder of this paper is organized as follows;
we first start with a description of the experimental set
up and then go to discuss the simulation parameters and
methodology. This is followed by a presentation of our
proposed measure and a review of the simulation
results. Finally conclusions and recommendations for
future research are presented.

2. Layout and Considered Configurations

In order to be able to study the interrelation between
daylighting performance and thermal performance and
explore the theoretical relationship proposed above, a
parametric model using Grasshopper for Rhino was
developed. The model is shown in Fig. 2 and is divided
into five main parts. The first portion of the definition
is used to control the various parameters used in the
simulation. The second part of the model is used to
modify the window to wall ratio of the typical room
used. The standard room used is based on the one
developed in Wagdy (2013) [9].

In this part of the model the window to wall ratio is
varied in a systematic method as described in Wagdy
(2013) [9], so that the various design parameters are
varied systematically to increase the increments of the
window to wall ratio. Firstly, the height is changed to the maximum value, then the width and finally the sill height are increased at certain increments to maintain unit step increases in the WWR.

This is shown in more detail in Fig. 3. The developed grasshopper model then makes use of the Diva interface to send the simulation to RADIANCE for a full analysis and results generation, which makes up the third part of the grasshopper definition. In the fourth part the grid and sensor values are calculated and finally in the last part the results are exported to excel.

It is important to note that a shading device is used that a constant shading angle is kept constant throughout our simulations as shown in Fig. 4. The two extreme cases of south and east facades are considered here, since they would tend to more clearly demonstrate the relationship between daylight and thermal performance.

Fig. 2 Model development window to wall ratio (WWR) variations.

Fig. 3 Model development window to wall ratio (WWR) variations.

Fig. 4 Shading geometry, this shading angle is constant for all cases.
Simulations are carried out and in total 17 cases are considered as can be seen in Fig. 3. For each case the solar irradiation is calculated at each of the room’s sensor points. In addition, for each case considered the Daylight Autonomy (DA) was calculated. Daylight Autonomy (DA) is one of a number of daylight metrics that consider the annual performance of a particular design. DA basically represented as a percentage of annual daytime hours that a given point in a space is above a specified illumination level [10].

The measure was originally proposed by the Association Suisse des Electriciens in 1989 and was later developed by Christoph Reinhart between 2001 and 2004 [11]. Daylight Autonomy considers the specific geographic location for a particular space and hence uses the actual weather information on an annual basis.

In addition, since it represents the times that artificial lighting may not be needed it is strongly related to electric lighting energy savings if the user defined a specific threshold that would bet based upon electric lighting criteria.

The designer is usually free to set a specific limit above which Daylight Autonomy is calculated. In our simulations we used a typical value for Daylight Autonomy threshold of 300 lux (DA300). The Daylight Autonomy percentage calculation represents how much of the floor area achieved 50% or more daylight autonomy in DIVA analysis.

\[
\text{Rooms } DA\% = \frac{(\text{No. of nodes})_{DA\%}}{\text{Total No. of Nodes}} \quad (1)
\]

Table 1 shows the different parameters used in running the simulation. The RADIANCE parameters are shown in terms of the number of ambient bounces and ambient divisions as well as other parameters. In addition, the different parameters used for the typical space are shown.

### 3. Results and Discussion

Coupled thermal and daylight simulations were first carried out for the 17 cases of different WWR to increase the solar irradiation and the lux-hours coming into the room. Figs. 5 and 6 shows the annual cumulative irradiation at each sensor point for all the 17 cases versus the average Daylight Autonomy values at those same sensor points. This is shown for the south and east facades separately.

The graphical percent values represent the percentage of the floor area that exceeds 300 lux for at least 50% of the time. The results follow the assumed shape discussed in Fig. 1. Note that there may be different sensor points, where higher irradiation values are realized, while achieving the same DA performance. This is due to the fact that points on the inside of the space in one of the cases for example may have the same daylight performance as another sensor point further out in another case.

![Fig. 5 Solar irradiation versus DA for South facing orientation at different sensor points for all 17 cases.](image-url)
It is also interesting to note that the variation in the east is more profound, i.e., that for the east façade points such as the ones we noted in different cases will result in wider variations in thermal irradiation with the same values for DA performance. This means that the gap in the assumed Fig. 1 is wider for the east façade compared to the south one. This is expected since in the east façade will have varying amount of direct radiation due to the movement of the sun compared to the southern façade which may have more uniform solar radiation falling on it.

In order to study the results further, Figs. 7 and 8 show the solar irradiation versus the DA for the south and east facing orientation for the 17 test cases. The results shown in these figures is basically the aggregated values of each of the sensor points for each case.

The average cumulative annual irradiation for all the sensor points for each cases is presented with the average DA performance for the sensor points in each case. As such there are 17 data points in each graph, one for the south facing façade and another for the east facing façades. Again the same trend expected as in figure 1 above, holds for the aggregated values of the test cases. In fact, one may be able to add a clear regression line between the solar irradiation as the dependant variable and the DA as the independent variable for both the south and each façades. For the east façade the linear regression equation is:

\[ y = 0.3247x + 5.1363 \]  \hspace{1cm} (2)

</tbody>
</table>

however that the degree of confidence limits of these regression equation will vary. For example for the east facing façade the R² value was 0.996. While the equation for the south facing façade was

\[ y = 0.2348x + 2.7396 \]  

The R² value for the south facing façade was 0.9841, which is slightly lower than that of the east façade. Therefore as noted the regression equations will vary
with firstly the degree of sophistication of the design parameters considered and secondly with the orientation of the façade. In any case a new proposed measure for the combined performance may be expressed as

\[
\text{Proposed Measure} = \frac{\text{Max}[LDA]}{\text{Irradiation}} \tag{4}
\]

This measure would reward higher daylight performance in terms of Daylight availability up to a maximum value of 100% while penalize higher irradiation values gained. As such cases on the inflection point of the curves in Figs. 7 and 8 would be considered superior and would achieve higher scores in our proposed measure as compared to cases which increase the irradiation without increasing the DA values. Table 2 shows details of some of the extreme cases.

4. Conclusion

Daylighting and solar thermal gains are often positively correlated. In particular, if a specific design achieves acceptable scores for the climatic-based daylighting measures, then it may be often the case that this can be on the account of exceedingly high thermal gains. In this paper a new metric is proposed that takes into account the total amount of lux-hours achieved throughout the year and the distribution of these lux-hours with the cooling and heating degree days for different time steps. There remains more work to be done.

The proposed metric is limited to convention fenestration and would not apply to complex fenestration systems where no correlation is expected between energy gains and lighting performance such spectrum selective fenestration systems. Large solar irradiation values mean extensive thermal gain loads which is an undesirable effect in hot zones most of the year. However, higher values are beneficial whenever the temperature drops below comfort levels. Therefore, it may still be wise to develop a performance index that can be calculated on seasonal basis, with the solar irradiation increase being favourable during winter only.
